Abstract

Changes in cortical thickness can be related to neuropsychiatric disorders and neurodegenerative processes. Previous studies have been conducted to characterize the pattern of changes in cortical thickness in several psychiatric diseases. The aim of the present study was to evaluate changes in cortical thickness with magnetic resonance imaging (MRI) in patients with bipolar disorder. Twenty-seven patients with bipolar disorder (14 male, 36.0 ± 16.2 years old; 13 female, 41.6 ± 10.7 years old) and 40 healthy controls (16 male, 36.0 ± 10.5 years old; 24 female, 37.0 ± 4.7 years old) underwent 3T MRI. Sagittal T1-weighted magnetization prepared rapid acquisition gradient echo images were acquired (voxel size, 1.33 mm^3 ; 128 slices; in-plane matrix resolution, 256×256 ; flip angle, 7° ; repetition time, 2530 ms; echo time, 3.39 ms; inversion time, 1100 ms). Cortical segmentation was performed using FreeSurfer 4.0.5. The results indicated both thinning and thickening of the cerebral cortex in patients with bipolar disorder compared with controls, depending on gender. Significant ($p < .01$) thickening was observed in the right hemisphere superior-parietal cortex in female patients with bipolar disorder, and significant ($p < .05$) thinning was observed in the left hemisphere caudal-anterior cingulate in male patients with bipolar disorder. The other regions did not show significant differences. The results suggest that an analysis of cortical thickness with MRI in patients with bipolar disorder may allow identification of areas that may be morphologically changed compared with controls. Demonstration of these alterations will elucidate the pathophysiology of bipolar disorder and may contribute to better therapies for this disorder. **Keywords:** Magnetic resonance imaging, neuroimaging, bipolar disorder, cortical thickness, morphometry.

Introduction

Bipolar affective disorder is a common, life-long progressive illness that normally begins in adolescence, with a lifetime prevalence of 1.0% (Lewinsohn, Klein, & Seeley, 1995). Several magnetic resonance imaging (MRI) studies have related morphological brain changes in bipolar disorder patients with healthy people, mainly in the frontal

lobe (Soares & Mann, 1997; Strakowski, Adler, & Del Bello, 2002; Drevets et al., 1997), ventricles and white matter (McDonald et al., 2004; Stoll, Renshaw, Yurgelun-Todd, & Cohen, 2000), subcortical regions (amygdala; Altshuler, Bartzokis, Grieder, Curran, & Mintz, 1998; Strakowski et al., 1999; Brambilla et al., 2001), hippocampus (Sax et al., 1999), basal ganglia (Brambilla et al., 2001; Aylward et al., 1994), and cortical regions (Lyoo et al., 2006).

Regarding the subcortical structural changes, inconsistent results have been obtained in the amygdala, hippocampus, and basal ganglia (Geuze, Vermetten, & Bremner, 2005), mainly attributable to differences in the acquisition protocols and volume measurement methods.

Several cortical brain regions are involved in emotional processing and emotional experience. Cortical thinning in these regions may reflect underlying neuropathological impairments in the cortical laminae (Zilles, 2000). Evidence suggests that these processes

are impaired in bipolar disorder. Measurement of cortical thickness may provide important insights into the specific characterization of neuroanatomical changes in this disease. Thickness changes in multiple prefrontal cortices have been found in patients with bipolar disorder (Lyo et al., 2006).

The morphometric measurement of the cortex is a difficult procedure because this structure is highly folded, which complicates manual determination of cortical thickness. Automated techniques have been developed to measure cortical thickness using high-resolution MRI and a surface-based reconstruction algorithm of the cortex (Fischl & Dale, 2000).

The aim of the present study was to measure cortical thickness in patients with bipolar disorder using automated surface-based analysis software (FreeSurfer) and to evaluate the structural changes in these patients. Demonstrating significant differences between the two groups in the brain areas responsible for emotional regulation using MRI as a noninvasive diagnostic method combined with automated cortical segmentation tools may aid in the diagnosis of bipolar disorder.

Method

Participants

All patients signed informed consent forms, and the study was approved by the clinical Institutional Review Board. Twenty-seven patients with bipolar disorder (14 male, 36.0 ± 16.2 years old; 13 female, 41.6 ± 10.7 years old) and 40 healthy controls (16 male, 36.0 ± 10.5 years old; 24 female, 37.0 ± 4.7 years old) were demographically matched. Patients were diagnosed with bipolar affective disorder by a senior psychiatrist (J.F.) using the Structured Clinical Interview for DSM-IV (First, Spitzer, Gibbon, & Williams, 1997), which was translated and adapted to Portuguese (Del-Ben et al., 2001).

MR image acquisition

T1-weighted images in the sagittal plane of all subjects were acquired using a 3.0 T imaging system (Verio, Siemens Medical, Erlangen, Germany) with a three-dimensional magnetization prepared rapid acquisition gradient echo (3D-MPRAGE) sequence (repetition time, 2530 ms; echo time, 3.39 ms; flip angle, 7° ; inversion time, 1100 ms; bandwidth, 190 Hz/pixel; in-plane matrix resolution, 256×256 ; slice thickness, 1.3 mm; number of slices, 128; voxel size, 1.3 mm^3 ; no parallel imaging technique; number of averages, 1; total acquisition time, 8 min 6 s). The image acquisition protocol was adapted from a protocol proposed by the Athinoula A. Martinos Center for Biomedical Imaging (Boston, MA, USA), which optimizes gray and white matter contrast (Fig. 1).

Figure 1. Three-dimensional T1-weighted images with high spatial resolution and good white matter/gray matter contrast are necessary for the analysis of cortical thickness.

Image processing and cortical thickness measurements

The T1-weighted images were transferred to a computer workstation (Mac Pro, Apple, Cupertino, CA, USA) with 8 GB of memory and two Quad-Core Intel Xeon processors (2 x 3.2 GHz). Cortical reconstruction and volumetric segmentation were performed with FreeSurfer v. 4.0.5 (Martinos Center, Boston, MA, USA; <http://surfer.nmr.mgh.harvard.edu/>; access February 5, 2010). The technical details of these procedures have been described previously (Fischl et al., 2002; Desikan et al., 2006). Briefly, this processing includes motion correction, removal of non-brain tissue using a hybrid watershed/surface deformation procedure, automated Talairach transformation, segmentation of subcortical white matter and deep gray matter volumetric structures (including the hippocampus, amygdala, caudate, putamen, and ventricles), intensity normalization, tessellation of the gray matter/white matter boundary, automated topology correction, and surface deformation and inflation of the cerebrum. Thickness maps are calculated automatically.

After registration of all cortical thickness maps of each subject to a standard space, the mean cortical thickness in a region-of-interest in the bipolar group and control group, differentiated by gender, was calculated and statistically compared.

Statistics

Statistical analysis was performed using the QDEC tool in the FreeSurfer software suite and R-software v. 2.9.0 (Auckland, New Zealand). Patients with bipolar disorder were demographically matched to controls, and differences in cortical thickness were analyzed using Student's *t*-test to detect significant differences in the mean cortical thickness in various cortical regions.

Results

Alterations in cortical thickness in patients with bipolar disorder are listed in Table 1. The regions shown in the table indicate the cortical regions with the greatest statistical differences between groups. Both cortical thinning and thickening can be seen in patients with bipolar disorder compared with controls. Additionally, the thinning and thickening depended on gender. Significant ($p < .01$) thickening was observed in the right hemisphere superior-parietal cortex in females with bipolar disorder, and significant ($p < .05$) thinning was observed in the left hemisphere caudal-anterior cingulate in males with bipolar disorder. The other regions did not exhibit significant differences between groups.

Figure 2 shows the statistical maps of significant differences in cortical thickness between patients with bipolar disorder compared with controls. The maps are overlaid on an inflated cerebrum in standard space (Talairach).

Discussion

In the present study, regions with thinning and thickening of the cortex were observed in patients with bipolar disorder compared with controls. In the male bipolar group, the caudal-anterior cingulate showed a significant ($p < .01$) difference, and in the female group, significant ($p < .05$) thickening was observed. Other regions showed differences in cortical thickness, but these differences were not significant ($p > .05$).

Lyoo et al. (2006) also used a surface-based reconstruction algorithm and found significant cortical thinning in bipolar disorder patients. In the left hemisphere, significant decreases in cortical thickness were observed in the middle frontal cortex (2.24 mm^3 vs. 2.38 mm^3), postcentral cortex (2.53 mm^3 vs. 2.74 mm^3), pregenual anterior cingulate cortex (2.93 mm^3 vs. 3.11 mm^3), dorsal anterior cingulate cortex (2.50 mm^3 vs. 2.68 mm^3), posterior cingulate cortex (2.45 mm^3 vs. 2.57 mm^3), and middle occipital cortex (1.90 mm^3 vs. 2.06 mm^3) between bipolar subjects and healthy controls, respectively. In the right hemisphere, significant decreases in cortical thickness were observed in the medial frontal cortex (2.49 mm^3 vs. 2.66 mm^3), postcentral cortex (1.95 mm^3 vs. 2.14 mm^3), angular cortex (2.39 mm^3 vs. 2.59 mm^3), and fusiform cortex (1.90 mm^3 vs. 2.05 mm^3) between bipolar subjects and healthy controls. These authors did not evaluate cortical thickness differences by gender, making comparisons with our results difficult. However, to emphasize the importance of evaluating groups by gender, although Lyoo et al. (2006) found a significant reduction in the posterior cingulate in patients with bipolar disorder, including both males and females, we found nonsignificant cortical thinning in the male group but significant thickening in the female group.

One limitation of the present study was the small number of demographically matched subjects, but from a statistical analysis standpoint, the number of subjects had sufficient statistical power. Future studies will require a larger number of subjects to further understand the

Figure 2. Statistical maps of regions showing significant differences overlaid on an inflated cerebrum that shows the regions where differences existed (either thicker or thinner) in patients with bipolar disorder compared with controls. The sidebar shows color-coded significance, ranging from $p < .01$ to $p < .001$.

Table 1. Cortical thickness in different brain regions in bipolar disorder patients and controls. The regions shown in the table are the cortical regions with the greatest significance.

Region	Cortical Thickness (mm ³ ± SEM)			
	Bipolar Disorder Patients		Controls	
	Female	Male	Female	Male
<i>Left Hemisphere</i>				
Superior parietal	1.816 ± 0.232	1.908 ± 0.247	1.972 ± 0.310	1.946 ± 0.270
Posterior cingulated	2.424 ± 0.291	2.198 ± 0.480	2.219 ± 0.465	2.453 ± 0.591
Lateral orbitofrontal	2.443 ± 0.623	2.518 ± 0.475	2.726 ± 0.448	2.485 ± 0.497
Lateral occipital	2.717 ± 0.370	2.659 ± 0.362	2.780 ± 0.396	2.667 ± 0.265
Caudal anterior cingulate	2.578 ± 0.412	2.255 ± 0.377	2.612 ± 0.324	2.634 ± 0.506
<i>Right Hemisphere</i>				
Isthmus cingulated	2.855 ± 0.711	2.690 ± 0.510	2.786 ± 0.584	2.442 ± 0.607
Caudal anterior cingulate	2.271 ± 0.581	2.255 ± 0.377	2.269 ± 0.515	2.236 ± 0.427
Superior parietal	2.057 ± 0.476	1.790 ± 0.398	1.734 ± 0.423	1.751 ± 0.419
Caudal middle frontal	2.593 ± 0.608	2.626 ± 0.366	2.773 ± 0.351	2.777 ± 0.435
Rostral middle frontal	2.055 ± 0.412	1.993 ± 0.322	2.152 ± 0.353	2.129 ± 0.376

pathophysiology of patients with bipolar disorder. Moreover, the specific clinical patient characteristics were not assessed in the present study, such as age of onset of bipolar disorder, illness duration, number of episodes, family history, or medications. Future studies should correlate these parameters, which may impact the results.

In conclusion, the *in vivo* analysis of cortical thickness using MRI combined with a surface-based reconstruction algorithm allowed the identification of morphologically altered brain areas in patients with bipolar disorder. Demonstration of these alterations will elucidate the pathophysiology of bipolar disorder and may contribute to better therapies for this disorder. Further studies with a greater number of demographically matched subjects will be necessary.
